Mesh Deformation based on Radial Basis Function Interpolation applied to Low Frequency Electromagnetic Problem

Thomas Henneron¹, Antoine Pierquin¹ and Stéphane Clénet¹

¹ Univ. Lille, Centrale Lille, Arts et Metiers ParisTech, HEI, EA 2697 - L2EP, F-59000 Lille, France

In order to take into account a modification of the geometry during an optimization process or due to a physical phenomenon, a deformation of the elements of the spatial discretization is preferable to conserve a conformal mesh and to apply the Finite Element (FE) method. To perform the displacement of nodes, interpolation method can be investigated in this context. In this paper, the Radial Basis Function (RBF) interpolation method is applied for low frequency electromagnetic problems solved by the FE method. A 2D magnetostatic example is considered to study the influence of the parameters of the RBF interpolation. To test the extension in 3D, a non destructive testing (NDT) problem is treated where the shape of the crack is modified by applying the proposed method.

Index Terms—mesh deformation, Radial Basis Function, finite element method, low frequency electromagnetism.

I. INTRODUCTION

TO study low frequency electromagnetic devices, the FE method is widely used. For problems with a parametrized shape or involving dynamic behavior of boundaries (dynamic magneto mechanical behavior for example), the FE mesh should fit the modification of the geometry. To solve this kind of problem, a simple approach consists in remeshing the geometry. Nevertheless, this method is not very efficient because it introduces a numerical noise and it breaks the natural link between two successive solutions in a time dependent problem. Different approaches based on interpolation methods have been developed in order to deform an initial mesh to take into account a shape modification. The idea is to impose the displacement for a set of nodes of the mesh or of points of the geometry and to determine the new coordinates for all other ones by an interpolation approach. In this context, the isogeometric analysis (IGA) [1] and the Radial Basis Function (RBF) interpolation method [2] can be investigated. For low frequency electromagnetic problems, for example, the IGA approach has been applied to optimize the shape of permanent magnets of a synchronous motor [3] or to parametrize the geometry of a piezoelectric device [4].

In this article, we propose to use the RBF interpolation method for the mesh deformation in the case of low frequency electromagnetic devices solved by the FE method. Initially, the approach has been developed in the case of flow fluid problem [5]. First, the RBF interpolation method is presented. Secondly, the mesh deformation based on the RBF is described. Thirdly, numerical experiments are performed in order to study the influence of the parameters of the RBF interpolation with a 2D magnetostatic problem. Finally, a 3D non destructive testing device is investigated for different shapes of the crack obtained from the RBF approach.

II. RADIAL BASIS FUNCTION INTERPOLATION METHOD

The RBF interpolation method is often used to compute an approximation $s(\mathbf{x})$ of a multivariable function $f(\mathbf{x})$. This

TABLE I
EXAMPLES OF RBF FUNCTION

Name	$\phi(\mathbf{x})$
Gaussian	$e^{-(\mathbf{x}/a)^2}$
Multiquadric	$\sqrt{1 + (\mathbf{x}/a)^2}$
Inverse quadric	$\sqrt{\frac{1}{1 + (\mathbf{x}/a)^2}}$
Thin plate spline	$\mathbf{x}^2 \log(\mathbf{x})$

approximation is expressed as a linear combination of basis functions ϕ . In a general way, we consider N_t training points such as $y_i = f(\mathbf{x}_i)$ for $i = 1, \dots, N_t$ with $\mathbf{x}_i \in \mathbb{R}^p$ and $y_i \in \mathbb{R}$. Then, for a new coordinate $\mathbf{x} \in \mathbb{R}^p$, the approximation of $f(\mathbf{x})$ is given by

$$f(\mathbf{x}) \approx s(\mathbf{x}) = \sum_{i=1}^{N_t} \alpha_i \phi_i(\mathbf{x}) \quad (1)$$

with $\phi_i(\mathbf{x}) = \phi(\|\mathbf{x} - \mathbf{x}_i\|)$,

where ϕ_i is a radial function depending on the Euclidian distance between \mathbf{x} and \mathbf{x}_i and α_i is its associated coefficient. The coefficients α_i are calculated using the N_t training points in order to verify

$$y_j = f(\mathbf{x}_j) = s(\mathbf{x}_j) = \sum_{i=1}^{N_t} \alpha_i \phi_i(\|\mathbf{x}_j - \mathbf{x}_i\|) \quad (2)$$

for $j = 1, \dots, N_t$.

Then, we can define a matrix system to be solved for the computation of α_i such as

$$\mathbf{Y} = \mathbf{G}\alpha \text{ with } \mathbf{Y} = [y_1, \dots, y_{N_t}]^t, \alpha = [\alpha_1, \dots, \alpha_{N_t}]^t \quad (3)$$

$$\text{and } \mathbf{G} = \begin{bmatrix} \phi_1(\mathbf{x}_1) & \dots & \phi_1(\mathbf{x}_{N_t}) \\ \vdots & \ddots & \vdots \\ \phi_{N_t}(\mathbf{x}_1) & \dots & \phi_{N_t}(\mathbf{x}_{N_t}) \end{bmatrix}.$$

The error of interpolation depends on the choice of RBF. Table 1 presents different examples of functions where a is a parameter fixed by the user. Others functions can be used for the RBF interpolation such as functions with compact

support [5]. In the case of vector function $\mathbf{f}(\mathbf{x}) \in \mathbf{R}^q$, the RBF method is performed for each component of $\mathbf{f}(\mathbf{x})$. Then, the approximation $\mathbf{s}(\mathbf{x})$ is

$$\mathbf{f}(\mathbf{x}) \approx \mathbf{s}(\mathbf{x}) = \begin{bmatrix} s^1(\mathbf{x}) \\ \vdots \\ s^q(\mathbf{x}) \end{bmatrix} \quad \text{with } s^j(\mathbf{x}) = \sum_{i=1}^{N_t} \alpha_i^j \phi_i(\mathbf{x}) \quad (4)$$

for $j = 1, \dots, q$.

In this case, it is necessary to compute $N_t \cdot q$ coefficients α_i^j .

III. MESH DEFORMATION BASED ON RBF INTERPOLATION

In the case of the mesh deformation, the function $\mathbf{f}(\mathbf{x})$ to approximate corresponds to a displacement. Its approximation based on the RBF interpolation method is noted $\mathbf{d}(\mathbf{x})$ with $\mathbf{d}(\mathbf{x}) \in \mathbf{R}^2$ or \mathbf{R}^3 in the case of a 2D or 3D problem. To perform the RBF interpolation, two sets of nodes are defined. The first \mathcal{N}_f is composed of nodes with imposed displacements. The second one \mathcal{N}_i corresponds to nodes whose the displacements are approximated. The cardinal of \mathcal{N}_f and \mathcal{N}_i is N_f and N_i respectively. The displacement is interpolated separately for each spatial direction. Each node is moved individually according to the interpolation function $\mathbf{d}(\mathbf{x})$. Then, if we consider a node $n_k \in \mathcal{N}_i$, the approximation of its displacement $\mathbf{d}(\mathbf{x}_k)$ is

$$\mathbf{f}(\mathbf{x}_k) \approx \mathbf{d}(\mathbf{x}_k) = \begin{bmatrix} d_x(\mathbf{x}_k) \\ d_y(\mathbf{x}_k) \\ d_z(\mathbf{x}_k) \end{bmatrix} \quad \text{with } d_u(\mathbf{x}_k) = \sum_{i=1}^{N_f} \alpha_i^u \phi_i(\mathbf{x}_k) \quad (5)$$

for $u = x, y, z$.

For a 2D or 3D problem, the number of coefficient α_i^u to be defined is $2N_f$ or $3N_f$ respectively. These coefficients are computed by (3) according to each spatial direction, the vector \mathbf{Y} of size N_f corresponds to the imposed displacement of nodes \mathcal{N}_f according to the considered direction. Then, the new coordinates of the node n_k is $\mathbf{x}_k = \mathbf{x}_{k0} + \mathbf{d}(\mathbf{x}_k)$ with \mathbf{x}_{k0} the original coordinates.

In order to illustrate the mesh deformation based on the RBF interpolation method, a simple academic example is used. The 2D spatial domain is rectangular shape discretized by triangle elements (fig. 1). The two sets of node \mathcal{N}_f and \mathcal{N}_i are introduced to perform the deformation (Fig.1.b). The displacement of the nodes of \mathcal{N}_f is imposed according to their x coordinates. Then, for a node $n_k \in \mathcal{N}_f$, the displacement along the axis y is imposed such as

$$d_y = \begin{cases} 0 & \text{if } y = 0 \\ -25 \cos(\pi/100x) & \text{if } y = 40 \end{cases} \quad (6)$$

The displacements of the nodes of \mathcal{N}_i are interpolated with Gaussian functions for the RBF. Figure 2.a presents the deformed mesh. As the displacement of a node is calculated independently from the other ones, it is necessary to verify the conformity of the deformed mesh. Then, we propose an indicator based on the comparison of the determinant of the initial and the deformed element. Thus, the indicator is $d_e = \det_{e-def} / \det_{e-init}$ with \det_{e-def} and \det_{e-init} the determinants of the deformed and initial element e . If the

indicator is positive for all elements, the deformation of the mesh is correct. If an element is shifted between both meshes and overlaps others elements, its indicator is negative and the deformed mesh is not conformal. The distribution of the indicator is presented in Fig. 2.b, it gives information of the deformation for all elements of the mesh.

IV. NUMERICAL EXPERIMENT

A. Presentation of the example

We consider a 2D magnetostatic example composed with 11840 1st order triangle elements. The device is composed by a stranded inductor supplied by a current, a magnetic core and a magnetic plate. The vector potential formulation is used to solve the problem, the strong formulation is

$$\text{curl} \left(\frac{1}{\mu} \text{curl} \mathbf{A} \right) = \mathbf{J} \quad (7)$$

with μ the magnetic permeability, \mathbf{J} the current density of the stranded inductor and \mathbf{A} the unknown potential. The mesh deformation is imposed on the plate, the boundary of mesh deformation is specified in fig. 3. In figure 4, the red and green nodes correspond to those of \mathcal{N}_f and the orange nodes to those of \mathcal{N}_i . The position of green nodes is fixed and the displacement of red nodes is imposed. The RBF interpolation method is performed onto the orange nodes. A rotation movement of 20 degrees in the clockwise direction is imposed for the plate. At first, the aim is to study the influence of the parameters of the RBF interpolation method on the mesh deformation. In a second time, local quantities are studied.

B. Influence of the iteration number

The RBF interpolation method can be applied iteratively. At each iteration, the method to calculate the new coordinates of the nodes is performed with the intermediate mesh

Fig. 3. Magnetostatic problem

Fig. 4. Definition of \mathcal{N}_f and \mathcal{N}_i

computed at the previous iteration. Then, a large deformation is decomposed in several smaller ones. Figure 5 presents the distribution of the deformation indicator for the last mesh after 1, 2, 4 and 8 iterations. Gaussian functions with $a = 1$ is used for the RBF. For 1 and 2 iterations, the deformation indicator

Fig. 5. Influence of the iteration number on the mesh deformation with Gaussian functions and $a = 1$

is negative for several elements, the mesh is not conformal in this case. With 4 and 8 iterations, the final meshes are close and conformal. Then, an iterative approach of the RBF interpolation method increases the robustness of the mesh deformation.

C. Influence of the choice of RBF

We compare the mesh deformation for three different RBF with 4 iterations. Gaussian, multiquadric and inverse quadric functions are considered with the same value for the parameter a ($a = 1$). Figures 6 and 5.c present the distributions of the deformation indicator for multiquadric and inverse quadric functions and for Gaussian functions respectively. For all

Fig. 6. Influence of the radial basis function on the mesh deformation

cases, the final mesh is conformal. The influence of functions is not very significant on our example. Nevertheless, we can observe that the mesh deformation is smoother with the inverse quadric function than with the two others.

D. Influence of the parameter a

The parameter a of functions presented in table I enables to adjust the domain of influence of nodes with imposed displacements on a node to be moved. Greater a is important, most influential is the displacement of node by nodes with a fixed displacement. Figures 7 and 5.c present the distributions of the deformation indicator for Gaussian functions with $a = 0.5$ and 1.5 for 4 iterations.

Fig. 7. Influence of the parameter a on the mesh deformation

E. Influence on local quantities

Figure 8 presents the distributions of the magnetic flux density. Gaussian and inverse quadric functions are applied for the RBF interpolation. The influence of the choice RBF is not so significant. In fact, the difference of the maximal magnitude is 0.2mT.

Fig. 8. Distribution of the magnetic flux density (T) for a rotation movement of the plate

V. APPLICATION

A 3D application example based on a NDT device is considered (Fig. 9) [6]. This consists in a stranded inductor supplied by a sinusoidal current, a magnetic core and a conductive plate with a crack. The electric formulation is used to solve the problem in the time domain, the strong formulation is

$$\text{curl} \left(\frac{1}{\mu} \text{curl} \mathbf{A} \right) + \sigma (\partial_t \mathbf{A} + \text{grad} \varphi) = \mathbf{J} \quad (8)$$

with σ the electric conductivity of the plate and φ the scalar electric potential defined within the plate. The mesh is composed of 203659 1st order tetrahedra. The aim is to study the difference of magnetic flux with and without crack. From the original mesh with an initial shape of the crack, the RBF interpolation method is performed to modify the geometry of the default. Inverse quadric functions are used for the RBF with 8 iterations to reach the final deformation (see IV-B). Figure 10 presents the distribution of the deformation indicator for a translation, a rotation and a sinusoidal deformation of the crack. For all cases, the deformed mesh is conformal. Figure

Fig. 9. Mesh of the NDT example

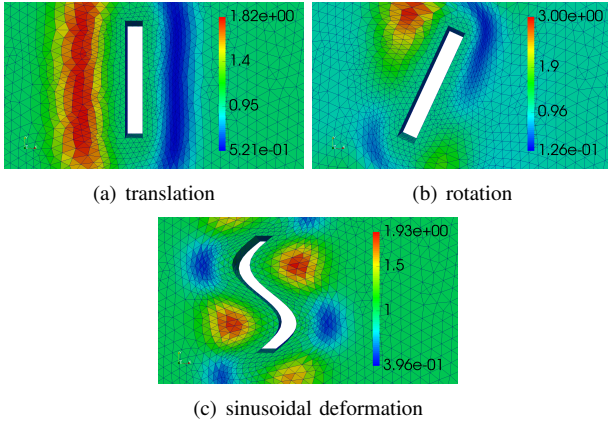

Fig. 10. Deformation indicator for three different deformations

11 presents the distribution of the eddy current density for the different shapes of the crack. Figure 12 presents the evolution of the difference of the magnetic flux flowing through the stranded inductor for different shapes of the crack. For the initial position and for a rotation of the crack, the evolution are close. The maximal magnitude is obtained with the crack translated from the initial position. In term of computational time, the mesh deformation required about 8.5s for 5576 nodes to be moved. This is inferior to the computational time necessary to solve one time step of the problem (10s).

VI. CONCLUSION

The RBF interpolation method has been developed with low frequency electromagnetic problem solved by the FE method. A 2D academic magnetostatic example has been used to study the influence of the parameters of the RBF interpolation. A deformation indicator has been introduced to verify the validity of the deformed mesh. Then, a 3D magnetodynamic problem based on a NDT device has been studied. Different shapes of the crack have been obtained from the deformation of the initial geometry of the default. From the studied examples, the RBF interpolation method seems to be an interesting approach for the deformation of the shape of electromagnetic device.
